Hydrothermal dolomitization of the carbonate Jurassic succession in the Provençal and Subbriançonnais Domains (Maritime Alps, North-Western Italy)

Dolomitisation hydrothermale de la succession carbonatée jurassique dans les zones Provençale et Subbriançonnaise (Alpes Maritimes, Nord-Ouest de l'Italie)

KEY WORDS. Hydrothermal dolomite, Provençal Domain, Maritime Alps, Jurassic limestones.

ABSTRACT. The present paper illustrates a straightforward case of hydrothermal dolomitization, affecting Jurassic platform limestones of the Provençal and Subbriançonnais Domains (Maritime Alps, North-Western Italy). Dolomitized bodies are randomly distributed within the host limestone, and are commonly associated with dolomite vein networks and tabular bodies of dolomite-cemented breccias discordant with respect to bedding. Main dolomite types are a finely to medium-crystalline replacive dolomite and a coarsely crystalline saddle dolomite occurring both as replacive and as cement. Stratigraphic constraints indicate that dolomitization occurred during the Cretaceous, in a shallow burial context, and was due to the circulation of hot fluids (temperature about 200 °C, as indicated by fluid inclusion microthermometry) through faults and related fracture networks. Hydrothermal dolomitization therefore indirectly documents a Cretaceous fault activity in the Maritime Alps segment of the European Tethyan passive margin.

MOTS CLÉS. Dolomite hydrothermale, Zone Provençale, Alpes Maritimes, calcaires jurassiques.

RÉSUMÉ. Cet article montre pour la première fois l'effet de dolomitisation hydrothermale sur des séries jurassiques de plate-forme dans les zones Provençale et Subbriançonnaise (Alpes Maritimes, Nord-Ouest de l'Italie). Les masses dolomitisées ont une distribution casuelle dans le calcaire hôte, et sont communément associées avec réseaux de veines dolomitiques et corps tabulaires de brèches à ciment dolomitique discordants par rapport à la stratification. Les typologies principales de dolomite comprennent une dolomite de remplacement à grain fin à moyen et une dolomite en selle à grain grossier. De fortes contraintes stratigraphiques indiquent que la dolomitisation a eu lieu dans le Crétacé, dans des conditions d'enfouissement très superficielles. Cette dolomitisation était liée à la circulation de fluides très chauds (environ 200 °C) à travers un réseau de failles et diaclases. La

dolomitisation hydrothermale est donc un argument indirect en faveur d'une activité tectonique crétacée dans les zones Provençale et Subbriançonnaise de la marge passive Européenne de la Téthys Alpine.

1. Introduction

Among the many facets of the so called "dolomite problem" (see Machel, 2004, for discussion and references), hydrothermal dolomite has been recently the object of interest and debate (Machel and Lonnee, 2002; Davies and Smith, 2006). In order for dolomite to be interpreted as hydrothermal not only a relatively high temperature of formation is to be proved but it should be coupled to inferred burial depths that cannot justify the calculated temperatures, insofar suggesting the upward advection of hot dolomitizing fluids (Machel, 2004).

In the stratigraphic successions of the Maritime Alps at the south-eastern termination of the Argentera Massif, a dolomitization of the Jurassic limestones was reported by those authors who dealt with these areas in the past decades (Campanino Sturani, 1967; Carraro et al., 1970; Malaroda, 1970) but neither detailed description nor attempts of interpretation were provided. Stratigraphic constraints, geometry and petrography of the dolomitized bodies, and isotope data and fluid inclusion microthermometry allow to reconstruct age, temperatures and burial depth for the dolomite of the Jurassic succession of the study area

The purpose of this paper, therefore, is to contribute to refine the understanding of the dolomitization process, by means of a case history, and, from a regional point of view, to evaluate the implications of the occurrence of this kind of dolomite on the tectono-sedimentary evolution of this part of the passive European Tethyan margin.

2. Geographic and geological setting

The study area is located in the north-eastern Maritime Alps (North Western Italy), between the Sabbione Valley to the west and the upper Vermentina Valley to the east, close to the village of Palanfrè (Fig. 1). This sector is composed of several tectonic units, presently superimposed along low-angle NW-SE striking Alpine tectonic contacts. Their geometrical position has been classically interpreted to reflect the paleogeographic position along the Mesozoic European paleomargin of the western Tethys, thus the lowest units have been classically attributed to the more external

65 Dauphinois Domain, and the overlying units to the more internal Subbriançonnais Domain (Carraro
 66 et al., 1970).
 67 More precisely, in the study area the main features of the Dauphinois succession are closely
 68 comparable to the Provençal ones, that are characterized by a reduced thickness and shallow water
 69 facies. In the following, we will refer to this succession as Provençal. It starts with Permian
 70 continental sediments that rest on the crystalline basement of the Argentera Massif and are
 71 characterized by marked thickness changes; they are followed by some tens of meters of Lower
 72 Triassic coastal siliciclastic deposits and Middle Triassic peritidal dolomitic limestones. A regional
 73 discontinuity surface corresponding to a Late Triassic-Middle Jurassic hiatus is followed by a thick
 74 (200-300 m) succession of Middle?-Upper Jurassic platform limestones. Locally, at the top of the
 75 Jurassic carbonates a few meters of Lower Cretaceous calcareous-marly deposits are preserved
 76 (Carraro et al., 1970).
 77 The basement of the Subbriançonnais succession is unknown as it is detached in correspondence of
 78 Upper Triassic shales. Above, a thick carbonate succession (200-300 m) of uncertain age (Early-
 79 Late Jurassic) is present, and shows the same features as the coeval Provençal interval. The
 80 Cretaceous succession is characterized by important lateral variations: it is absent in the south-
 81 eastern sector (Bec Matlas, Fig. 1), while it reaches thicknesses of one hundred meters in the north-
 82 western sector (M. Pianard, Fig. 1). Here, it is formed by bioclastic limestones, probably of Early
 83 Cretaceous age, and by Upper Cretaceous marly limestones and sandy limestones (Zappi, 1960).
 84 In both Provençal and Subbriançonnais units, the top of the Mesozoic succession is truncated by a
 85 regional unconformity corresponding to a hiatus spanning the Late Cretaceous-Middle Eocene.
 86 Above the unconformity, the Alpine Foreland Basin succession consists of the Middle Eocene
 87 Nummulitic Limestone, followed by the hemipelagic Upper Eocene *Globigerina* Marl and by the
 88 Upper Eocene-Lower Oligocene turbidite succession of the Grès d'Annot (Sinclair, 1997).
 89 The tectonic history of the above described succession was marked in Mesozoic times by syn-
 90 sedimentary extensional and strike-slip tectonics (Bertok et al., 2011; 2012). Since Late Eocene-
 91 Early Oligocene the paleo-European continental margin was then progressively involved in the on-
 92 going formation of the Alpine belt. All the study successions underwent at least three deformation
 93 events well recorded at regional scale, firstly with outward (SW) brittle-ductile thrusting and
 94 superposed foldings, NE back-vergent folding and then with S-ward brittle thrusting and flexural
 95 folding. The overall regional kinematic was displayed in a transpressional regime with important
 96 strain partitioning of contractional vs. strike-slip related structural associations (Piana et al., 2009),
 97 as evidenced by the occurrence of a post-Oligocene NW-SE Alpine transcurrent shear zone
 98 (Limone Viozene Zone, LIVZ) extending for several kilometres from Tanaro valley to the study

99 area. The LIVZ dies out NW-ward some kilometers south of Gesso Valley where it merges with
100 the E-W strike-slip shear zone system known as “Stura Fault” of Ricou and Siddans (1986). Despite
101 the high amount of finite deformation in the study area, strain partitioning allowed preservation of
102 most of the primary stratigraphic features and geometrical relationships.

103 The occurrence of dolomitization affecting the Jurassic limestones of both Provençal and
104 Subbriançonnais units in the study area was already reported, although very briefly, by previous
105 authors (Campanino Sturani, 1967; Carraro et al., 1970; Malaroda, 1970). However, no description
106 of the stratigraphic and petrographic features of the dolomitized sediments was given and no
107 explanation was proposed regarding their genetic processes.

108

109 **3. Methods**

110

111 Field work and geological mapping were performed in order to reconstruct the geometry, extension
112 and distribution of the dolomitized bodies. Petrographic studies were carried out on selected
113 samples by optical microscopy and cathodoluminescence aimed to distinguish different dolomite
114 generations. Fourteen microdrilled samples were measured for their carbon and oxygen isotope
115 composition following the method after McCrea (1950) in which carbonate powder is reacted in
116 vacuum conditions with 99% ortho phosphoric acid at 25 °C (time of reaction: 4 h for calcite and 6–
117 7 h for dolomite) using a Finnigan MAT 252 mass spectrometer (MARUM Stable Isotope
118 Laboratory, Bremen, Germany). The isotopic ratios are expressed as $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ per mil values
119 relative to the VPDB standard (precision $\pm 0.05\text{‰}$). Petrography and microthermometry of primary
120 fluid inclusion assemblages on saddle dolomite were performed, using a Linkam THMSG600
121 heating-freezing stage coupled with an Olympus polarizing microscope (100x objective) at the
122 Department of Earth Sciences, University of Torino (Italy), in order to record the homogenization
123 temperatures.

124

125 **4. Host rocks**

126

127 The studied dolomite occurs mainly within the Jurassic limestones of both Provençal and
128 Subbriançonnais units; locally, however, it also affects tectonic slices of Middle Triassic peritidal
129 carbonates present in the LVDZ. The Jurassic limestones are organized in ill-defined dm- to m-
130 thick beds and mainly consist of mudstones to packstones with echinoderm fragments; the upper
131 portion is made up of bioclastic limestones, ranging from packstones to rudstones and boundstones,

rich in corals, nerineid gastropods, thick-shelled bivalves, and stromatoporoids. The stratigraphically highest dolomitized beds are locally represented by lagoonal charophyte-rich wackestones. The lower portion of the dolomitized succession was attributed to the Middle-Upper Jurassic (Carraro et al., 1970), whereas the upper part was dated to the Kimmeridgian-Tithonian by Campanino Sturani (1967). However, lagoonal charophyte-rich beds analogous to those observed in the study area, are reported in the same stratigraphic position in the Provençal successions of the Nice Arc, and are dated to the middle-late Berriasian (Dardeau and Pascal, 1982). At present, the study of the charophyte associations is in progress, in order to verify the possible Berriasian age of the top of the dolomitized limestones.

141

142 **5. Dolomite features**

143

Dolomitization shows a great variability in the study area. Some Jurassic limestones are only partly dolomitized with development of scattered crystals with euhedral habits (planar fabric of Sibley and Gregg, 1987) (Pl.1A). In other cases dolomitization is more intense and follows a more or less complex network of randomly oriented veins (100 μm - to 2 mm-thick on average) (Pl.1A, B). Veins locally are more closely spaced and arranged along sub-vertical, cm- to dm-wide, zones. No significant geometric relations with the main macroscale Alpine tectonic features (such as faults, master joints or hinge zone of flexural folds) have been observed. Dolomite veins crosscut the bedding and are displaced by younger calcite vein system of tectonic origin. Cm-wide, subvertical tabular bodies of dolomite-cemented breccias with partially dolomitized limestone angular clasts also occur (Pl.1B). Mm- to cm-sized irregularly shaped cavities are geopetally filled up with a basal fine-grained dolomite sediment and by coarse dolomite and calcite cements (Pl.1C) and are interpreted as the result of localized dissolution of the enclosing limestone. Fully dolomitized rocks, with a complete obliteration of primary fabrics, occur as small (dm- to m-wide) masses randomly distributed within the partially dolomitized limestones and show a variety of structures documenting complex transformations. Three most representative types can be recognized:

Type 1: Quite homogeneous finely to medium crystalline dolostones, resulting from pervasive replacement of the Jurassic limestones.

Type 2: Clast-supported breccias made up of clasts of type 1 dolostones (Pl.1D). Clasts range from centimetric to decimetric in size, subrounded to angular in shape. Locally, angular clasts show a jigsaw puzzle arrangement. The voids between the clasts are filled up with mm-thick rims of a coarsely and very coarsely crystalline (up to a few millimetres) whitish dolomite cement, followed by a dark sparry calcite cement plugging the remaining pores.

166 Type 3: Clast-supported breccias, entirely composed of mm- to cm-long and 100 μm - to 2 mm-
167 wide, plate-like, clasts of medium to coarsely crystalline dolomite, strongly resembling the veins
168 crosscutting the host limestones. The voids between the clasts are filled up with a dark sparry
169 calcite cement.

170 Dolomitization, both partial and complete, crosscuts the host limestone bedding. It affects discrete
171 rock masses that are randomly distributed, and is not constrained to specific stratigraphic intervals.

172 From a microscopic point of view, two dolomite types may be distinguished. One is finely to
173 medium-crystalline, non planar to planar-s (Sibley and Gregg, 1987), inclusion-rich, and occurs
174 only as replacive dolomite. It shows a moderate, purple-red cathodoluminescence. The second type
175 is coarsely- to very coarsely-crystalline, and shows the typical features of saddle dolomite (curved
176 crystal faces, sweeping extinction) (Pl.1C). The alternation of more and less inclusion-rich bands
177 outlines different growth stages. A well-defined zonation is also recognizable in
178 cathodoluminescence: a moderate purple-red zone is followed by a non-luminescent zone with thin
179 red hairlines, in turn overlain by a second moderate purple-red zone. It occurs both as replacive and
180 as void-filling dolomite, the latter giving rise to mm-thick rims fringing dissolution cavity walls and
181 breccia clasts.

182 O isotopes of both dolomite types show values ($\delta^{18}\text{O}$ ranging from -4 to -6 ‰ PDB: Fig. 2) clearly
183 more negative than seawater for dolomitizing fluids. More indicative data come from
184 microthermometric analyses of a selection of primary fluid inclusions on saddle dolomite. Although
185 this study is still in progress and it has not been conducted systematically on all the samples, more
186 than 30 homogenization temperatures measured on a selection of 4 samples, show a relatively tight
187 distribution, ranging from 170 to 220 °C, with the highest frequency around 200 °C. The
188 determination of the fluid salinity has not been possible so far because of the small diameter of the
189 fluid inclusions (few micrometers), that make difficult the observation of the complex phase
190 transitions during freezing and melting of the fluid.

191

192

193 **6. Reworked dolomite**

194

195 The base of the Middle Eocene Nummulitic Limestone, resting on the regional unconformity, is
196 locally represented by a m-thick bed of clast-supported conglomerate with dm-sized clasts of
197 limestones and coarsely crystalline dolomites. The conglomerate is followed by a several m-thick
198 succession of dm-thick normally graded beds, made up of conglomerates to arenites; clasts and
199 grains consist of dolomitic rocks and dolomite crystal fragments (Fig. 3). Clasts commonly show

bivalve borings. Petrographic features of clasts and grains clearly document that they represent fragments of the underlying dolomitized limestones.

The occurrence of dolomitic clasts in the lower portion of the Nummulitic Limestone was already reported by Campredon (1977) who, however, did not recognize their provenance from the dolomitized Jurassic succession.

7. Discussion and conclusions

7.1. Age of dolomitization

Although no direct dating is available, timing of dolomite formation is well constrained by undisputable stratigraphic evidence. The age of the youngest dolomitized sediments documents that dolomitization cannot be older than Kimmeridgian-Tithonian (Campanino Sturani, 1967) or even Berriasian on the basis of the newly recognized charophyte-rich beds.

The occurrence of clasts and grains of the dolomitized limestones within the basal levels of the Nummulitic Limestone, conversely, states that dolomitization cannot be younger than the Bartonian as indicated by the *Nummulites* association usually found in the Nummulitic Limestone (Campredon, 1977; Varrone and Decrouez, 2007). More precise data come from the observation of Cretaceous sediments of the Provençal Domain in the study area. They are generally referred to the lower Lower Cretaceous (Neocomian: Carraro et al., 1970) and, in none of the limited and scattered outcrops available in the study area, are dolomitized. This allows to further restrict the dolomitization event within the Early Cretaceous

7.2. Dolomitization process

The geometric (partially dolomitized bodies and dolomite-filled veins crosscutting host limestone bedding), petrographic (saddle dolomite, indicating temperatures higher than about 60 °C; Radke and Mathis, 1980), and geochemical ($\delta^{18}\text{O}$ systematically lower than -4‰ PDB) features of the dolomite, together with preliminary data from primary fluid inclusions (homogenization temperature values around 200 °C), attest that dolomitization took place after the deposition of the whole package of Jurassic limestones, and that dolomitizing fluids were hot and flowed mainly through fractures and veins. Dolomite precipitated both along such fracture systems and replaced, partially or completely, non-fractured volumes of carbonate sediments (type 1 dolostone). This clearly shows that at least part of the host Jurassic limestones were still permeable enough to allow

a diffuse flux of dolomitizing fluids. This could suggest that dolomitization took place in an early stage of diagenesis, once again pointing to the Early Cretaceous. In this frame, type 2 dolomite breccias resulted from disruption of fully dolomitized limestones, due to the upward flux of overpressurized fluids whereas type 3 dolomite breccias document a thorough dissolution of a veined host limestone and the consequent collapse of the isolated dolomite vein fills.

In order to reconstruct the diagenetic environment of such dolomitization, the burial history of the Jurassic limestones must be taken into account. The occurrence of reworked dolomite clasts, commonly bored, within the basal Nummulitic Limestone interval clearly documents that in the Bartonian the Jurassic limestones, already dolomitized, were exposed on rocky coasts where they could be colonized by endolithic organisms and eroded. Cretaceous to Lutetian sediments are missing or very thin all over the study area. Moreover, they are completely missing as clasts in basal Eocene conglomerates, and the underlying unconformity is never associated to evident angular geometrical relationships. All these lines of evidence lead to conclude that if a Cretaceous-Lutetian sediment package had been deposited on top of the Jurassic limestones, it was surely thin enough as to be removed without leaving any trace before the Bartonian transgression. Further to the NW, at the north-western edge of the Argentera Massif, a Turonian unconformity, associated with slump-scars and chaotic deposits and covered by platform-derived redeposited limestones of late Turonian to Campanian age, is known in literature within the basinal Calcarei del Puriac (Sturani, 1962; Carraro et al., 1970; Bersezio et al., 2002). This documents different kinds of erosional processes (gravity sliding and platform shedding) during the Late Cretaceous. However, in coeval basinal sediments, cropping out close to the study area, no evidence of these phenomena occurs, which supports the hypothesis of the substantial primary absence of Cretaceous sediments in the studied successions. A very shallow burial environment can thus be argued for the Jurassic limestones at the time of their dolomitization.

From the foregoing considerations it follows that the dolomitizing fluids were at a significantly higher temperature than the ambient temperature of the host rocks, and thus they can be considered true hydrothermal fluids (*sensu* Machel and Lonnee, 2002; Davies and Smith, 2006). The spatial arrangement of the vein network, the occurrence of the breccia bodies, and their features point to a hydrothermal system characterized by several dolomitization pulses separated by hydrofracturing processes. The latter were due to the abrupt expulsion of overpressured fluids raising up along main fluid-flow pathways, likely represented by high-angle faults and related fracture systems. Hydraulic fracturing was commonly associated to dissolution of the host limestone (documented by geopetally filled cavities and type 3 breccias) and followed by dolomite precipitation (cementation of veins and cavities and replacement of the host limestone). This suggests that fluid composition was

undersaturated with respect to calcite and oversaturated with respect to dolomite. If the overall picture of a superficial hydrothermal system is supported by field and laboratory data, further geochemical analyses are required in order to better define origin, composition and evolution through time of the dolomitizing fluids and to understand what caused precipitation of the sparry calcite cement which represents the last stage of filling of the still open pores.

7.3. Regional implications

The recognition of the described dolomite bodies has also important regional implications. Hydrothermal dolomitization indirectly documents a fault activity during the Cretaceous roughly along the transition zone between the Ligurian Briançonnais and the Provençal Domains. Structural and stratigraphic evidence of tectonic activity since Early Cretaceous has been indeed recognized in the adjacent External Ligurian Briançonnais Domain (Bertok et al., 2012), where approximately coeval, although less intense, dolomitization processes are known (Bertok, 2007).

7. Acknowledgments

The authors thank Simona Ferrando (Dipartimento di Scienze della Terra, Università di Torino) for guidance and assistance in fluid inclusion microthermometry. Thierry Dumont and an anonymous reviewer provided useful suggestions which improved the manuscript. A financial contribution by Italian Association for Sedimentary Geology (GeoSed) to L. Barale (2011) is kindly acknowledged.

 364 by a mm-thick rim of whitish dolomite cement. Remaining voids are plugged by a sparry, grey to
 365 black, calcite cement. Pencil tip for scale, on the left, is 1.5 cm long.

366 Pl. 1. A. Échantillon de calcaire jurassique montrant différents degrés de dolomitisation. La partie
 367 gauche est seulement partiellement dolomitisée, avec des cristaux euhédraux dispersés de dolomite;

368 la partie droite est entièrement dolomitisée, tandis que dans la partie centrale la dolomitisation suit
369 un réseau de veines. B. Partie supérieure des calcaires jurassiques partiellement dolomitisés: noter
370 la juxtaposition, à l'échelle centimétrique, de bandes de roche avec réseaux de veines dolomitiques
371 diversement orientées et de corps tabulaires de brèches à ciment dolomitique. C. Vue en lame mince
372 d'une cavité bordée d'un ciment de dolomite en selle et remplie d'un ciment calcitique. Noter les
373 faces courbes des cristaux de dolomite en selle et leur zonage. D. Brèche à support clastique avec
374 clastes entièrement dolomitisés et revêtus d'une frange millimétrique de ciment dolomitique
375 blanchâtre. Les vides résiduels sont remplis d'un ciment de calcite sparitique, de couleur grise à
376 noire. La pointe de crayon sur la gauche mesure 1,5 cm de longueur.

377

378 Fig. 2. $\delta^{18}\text{O}$ versus $\delta^{13}\text{C}$ crossplot of pore-filling calcite (empty squares) and saddle dolomite (black
379 dots). As a term of comparison, dolomites formed at surface in marine environments display
380 isotopic values ranging approximately from +1 to +3 ‰ VPDB for both $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ (Tucker &
381 Wright, 1990).

382 Fig. 2. Graphique combinée avec les rapports $\delta^{18}\text{O}$ et $\delta^{13}\text{C}$, mesurés sur la calcite (carrés vides) et la
383 dolomite en selle (points noirs) de remplissage des pores. Pour comparaison, la dolomite formée à
384 la surface dans des environnements marines montre des valeurs isotopiques compris entre +1 to +3
385 ‰ VPDB environ pour $\delta^{18}\text{O}$ et $\delta^{13}\text{C}$ (Tucker & Wright, 1990).
